Keywords: Research; Onchocerciasis; Elimination; Ivermectin; Transmission

Short Communication

Onchocerciasis is one of the five diseases referred to as preventive chemotherapy- Neglected Tropical Diseases (PC-NTDs). It affects 37 million people in 31 African countries as well as 3 countries in the Latin America and several areas in Yemen. Nigeria has the highest endemicity among countries responsible for 99% of infection globally. Blindness and severe skin manifestations are two major effects of the disease on affected populations with severe effects on affected communities. The disease is significantly a disease of the poor with economic implications resulting in further impoverishment of affected communities, a challenge to the achievement of SDGs 2 and 3 and national developmental goals. The main strategy for control in endemic countries is by mass ivermectin (Mectizan®) distribution. Mass distribution of ivermectin in Nigeria began in 1991 following surveys that determined the extent and intensity of onchocerciasis in Kaduna State [1,2]. The large scale distribution that began in Kaduna State was through community based method through a tripartite agreement between Sight savers, Kaduna State Ministry of Health and National Eye Centre Kaduna to ensure delivery to all endemic communities [2]. Nigeria has been administering ivermectin annually on a mass scale for over two decades and the status of transmission of the disease or impact of annual drug administration on disease transmission needs to be assessed to determine stoppage of annual MDA in line with the global road map and target for the elimination of the disease. Research efforts have resulted in use of molecular biology technique of PCR pool screening of the Samarium vector fly to ascertain status of transmission in transmission zones as well as the use serological method using ov-16 antigen to detect infection among children <10 years old by the use of Dried Blood Spots (DBS) and ELISA and also rapid detection of antibody in whole blood through the use of Diplex kit. Currently according to O'Hanlon et al. [3] national control

programmes in the former OCP and the WHO African Programme for Onchocerciasis Control (APOC) are shifting their focus from morbidity control to elimination of the infection where feasible through community-directed treatment with ivermectin (CDTI) which is in three phases according to the guidelines for stopping mass drug administration and verifying elimination of human onchocerciasis [4].

Phase 1: The intervention or treatment phase which is characterised by regular ivermectin treatment with a minimum requirement of 80% therapeutic coverage. This phase typically lasts at least 12-15 years, corresponding to the reproductive lifespan of the adult worm when exposed to drug pressure.

Phase 2: This phase immediately follows the intervention or treatment phase which is referred to as the "post treatment surveillance". This typically lasts 3-5 years.

Phase 3: This starts at the end of the 3-5 years of "post treatment surveillance" and is known as post elimination surveillance. The results of the current efforts are being awaited to determine the effectiveness of ivermectin in the elimination of onchocerciasis in one of the most endemic countries for onchocerciasis.

The results of the current efforts are being awaited to determine the effectiveness of ivermectin in the elimination of onchocerciasis in most endemic and populous country in West Africa.

Your next submission with Juniper Publishers

will reach you the below assets

- Quality Editorial service
- Swift Peer Review
- Reprints availability
- E-prints Service
- Manuscript Podcast for convenient understanding
- Global attainment for your research
- Manuscript accessibility in different formats

(Pdf, E-pub, Full Text, Audio)

- Unceasing customer service
