Abstract

Rabies infection is one of the fatal zoonotic encephalitis and caused by neurotropic viruses in the genus Lyssavirus, family Rhabdoviridae. Rabies virus is unique because the virus replicates in nervous system and sheds from saliva when its host is stimulated to bite. The virus escapes from responses of the immune system with some mechanisms as much as possible. So far, many studies have been conducted to identify the methods of escaping the virus from the immune system. This mini-review study discusses about some distraction rabies strategies to escape from immune system.

Abbreviations: BBB: Blood-Brain Barrier; CMI: Cell-Mediated Immune; CHUK: Conserved Helix-Loop-Helix Ubiquitous Kinase; CNS: Central Nervous System; G: the Rabies virus Glycoprotein; IFN-1: Interferon Type I; IKBKB: Inhibitor of Kappa Light Polypeptide Gene Enhancer in B-cells, Kinase beta; IRF-9: Interferon Regulatory Factor-9; ISG: Interferon-Stimulated Gene; ITK: IL2-Inducible T-cell kinase; JAK: Janus Kinase; MAVs: Mitochondria Antiviral Signaling Protein; MYD88: Myeloid Differentiation Primary Response 88; NCAM: Neuronal Cell Adhesion Molecule; p75NTR: p75 Neurotrophin Receptor; PIK3CG: p110γ subunit of class-I PI3-Kinase; PEP: Post-Exposure Prophylaxis; PrEP: Pre-Exposure Prophylaxis; PRRs: Pathogen Recognition Receptors; RAF: Rapidly Accelerated Fibrosarcoma; RV: Rabies Virus; RLR: The RIG-like Receptor; ssRNA: Single-Stranded RNA; STAT: Signal Transducers and Activator of Transcription; TBK-1: Serin-Threonine Protein Kinase-1; TLRs: Toll-Like Receptors

Introduction

Rabies virus (RV) causes a zoonotic and fatal infectious disease among all warm-blooded animals including humans that already do not acquire immunity against rabies [1,2]. Rabies virus as a negative-sense, single-stranded RNA (ssRNA) virus is a type species of the Lyssavirus genus of the Rhabdoviridae family. Rabies is cause of more than 59,000 deaths annually worldwide. The disease is endemic in most parts of the world, especially in Asia and Africa. In addition, this virus is capable of infecting livestock and creating financial damage [3-5]. Therefore, it is one of the major health problems in every community. So far, many studies have been performed to identify the methods of escaping the virus from the immune system. This mini-review study discusses about some distraction rabies strategies to escape from immune system.

Pathogenesis of Rabies

Infected animals carrying the virus in their saliva and in the final stages of the disease they transmit the virus to other sensitive animals or humans usually via biting. Unusual transfer methods such as organ transplant and aerosol (for example in infested bat caves) have also been reported in some human rabies cases [6]. At the first, the viruses replicate in myocytes, at the wound site [7]. Therefore, viruses reach to the brain via reverse axonal transport and finally encephalitis occurs. Rabies viruses have a different pathogenesis than other viruses, the virus enters to central nervous system (CNS) by escaping the immune system and causes pathogenesis [8]. The infection incubation period is varying from around 7 days to 3 months. Significant variance in the incubation period occurs due to difference in amount of the virus which introduced to the wound, severity and distance of the wound to CNS [9]. Direct inoculation of the virus into the nerve leads to a shortening of incubation period due to presence of several bite at different areas such as the neck and head [9].

Several molecules have been described on the nerve cells surface, which need to facilitate the virus entry into the cells as receptors such as the muscular family of nicotinic acetylcholine receptor (nAChR), neuronal cell adhesion molecule (NCAM), and p75 neurotrophin receptor (p75NTR) (Figure 1). The nAChR is the most important receptor for RV to enter to neuromuscular system [10]. Differences in these receptors affect the sensitivity of different
species to the rabies. The axonal transport occurs at a rate of 12 to 24 mm per day. On the other hand, the rapid axonal movement by microtubule-dependent motors and slow axonal movement via actions are mediated in this transport. Laboratory experiments showed the Colchicine effect on the virus axonal movement by destruction of microtubule factors. As a result, the drug leads to a slow transportation during axon that can effectively prevent spread of the virus [11]. As the virus reaches to CNS, neurological signs appear in two forms: classic encephalitic (furious) rabies or paralytic (dumb) rabies. Furious rabies, which occurs in 80% of patients, is well recognized with aphasia, incoordination, paresis, paralysis, hydrophobia, aerophobia, larynx spasms, confusion, delirium, hallucinations, hyperactivity to aerophobia and seizures [12]. Fourteen days after the onset of symptoms, death occurs due to cardiac arrhythmia and cardiopulmonary arrest [13]. In dumb rabies, an early sign is organ weakness with no loss of consciousness. This weakness begins at the site of the bite and spreads rapidly to other organs. Finally, paralysis spreads to the respiratory system and can cause death by asphyxia or choking. Patients can survive longer with dumb rabies than with furious rabies, persevering for up to 30 days [14].

The pathogenicity of rabies virus depends on the presence of an antigenic determinant on the viral glycoprotein (G) (for example, arginine or lysine position in 333aa of two different strains (ERA and CVS)). The glycoprotein is essential for integrity of an antigenic determinant and rabies virulence in adult mice. In addition, the lysine mutation at position 330 of the glycoprotein destroys virus infiltration into motor-sensory neurons after muscle inoculation [15].

**Intrinsic Immunity Performance**

First defense line in body against the pathogenic factor is the intrinsic immunity. The intrinsic immunity cells produce different cytokines such as interferon α/β and chemokines, which leads to activation of the complement and absorption of phagocytes including neutrophils and macrophages to the site of infection [16]. According to numerous studies, toll-like receptors (TLRs) are the best pathogen recognition receptors (PRRs) as part of the intrinsic immune response. Toll-like receptors expression in neurons has not been reported in normal conditions, until now. However, it has been observed that the human neurons express the TLR-3 molecule when are infected with some viruses such as RV. Beta interferon, chemokines and inflammatory cytokines are produced from infected cells by stimulating this receptor. The studies indicate that in rabies-infected neurons, the receptor contributes to development of some inclusion bodies (IBs). These IBs consist of viral N and P proteins. Experiments on the mice indicate that these IBs are not developed in absence of the TLR3 receptor. On the other hand, as it was mentioned, interferon β affects HLA-G expression and inhibits its immune function [16,17]. When some kinases (Tyrosine or Serine), including the p110γ subunit of class-I PI3-kinase (PIK3CG), IL2-inducible T-cell kinase (ITK), inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase beta (IKKB) and rapidly accelerated fibrosarcoma (RAF)-1 were under-expressed, observed a dampening in the inflammatory response. In addition, up-regulation of anti-inflammatory genes such as cell proliferatory proteins and conserved helix-loop-helix ubiquitous kinase (CHUK), N-Ras and K-Ras proto-oncogenes can influence the inflammatory response. Viral infected cells naturally upregulate some genes such as; IRF3, IRF7 and IFNB1, which could not stimulate an immune response with activation of the viral phosphoprotein. Furthermore, AKT activation (including IRF3 and IRF7) could change inflammatory macrophages to anti-inflammatory [18].

A low level of immune response is seen in victims of rabies. Rabies virus can escape immune responses using unique mechanisms and leads to death in non-vaccinated individual [2]. In general, it can be said that limitation of the inflammation by rabies virus infection may occur as follows: reduction of leukocyte, monocyte and macrophage insertion into the nerve...
tissue; maintaining the inability to pass the blood-brain barrier (BBB) to penetrate the CNS; minimizing the release of neurotoxic molecules that can maintain the function of the nervous system and host survival [19,20].

Adaptive Immune Response

Second line of defense, which acts after innate immunity, is adaptive immunity. Formation of an adaptive immune response against a microorganism is always created in the peripheral lymphoid tissue. Nerve tissue is free of lymphatic organs.

Cell-Mediated Immune (CMI) Response

Cellular immunity plays a key role to eliminate viral invasion and inhibited the access of RV to the peripheral nervous system (PNS) at the beginning of infection. However, blood brain barrier is a big challenge for CMI. In addition, expression of the human leukocyte antigens (HLA)-G molecules on neuronal cells by the production of interferon beta leads to converting naïve human T cells to regulatory T cells and production of inhibitory cytokines such as interleukin 10 leads to cellular immunosuppression [11,21].

Neutralizing Antibodies

Humoral immune system plays an important role against the rabies virus. When RV enters to body of immune individuals, neutralizing antibodies can neutralize viral infectivity and prevent adsorption of virus to neuronal cells. Studies indicated that non-immune individuals cannot produce appropriate level of neutralizing antibodies when affected by RV, thus the virus enters to nerve. Actually, neutralizing antibodies is produced in peoples who received the vaccine and in people who survived the disease (rarely) [11].

Apoptosis

Neurotropic viruses also cause cell death due to apoptosis or necrosis. Apoptosis is the main defense mechanism against the cells infected with the virus, and it prevents the virus spread in the body. Apoptosis of the virus-infected cells are directed by the cytopathic T cell and cytokines such as TNF-α, perforin, granzyme and Fas-FasL (Fas Ligand) reaction. Instead of being a host defense mechanism for the elimination of infected neurons, apoptosis could be specifically inhibited by RABV as an immune subversive strategy. As a strategy for neuro-invasiveness of the street RV strains and progression through the nervous system, the virus suppresses early apoptosis in neuronal cells via up-regulation of AKT2 and AKT3 by G viral proteins and in turn, provides pre-apoptotic conditions in the immune cells via high representation of FAS Ligand [18]. In fact, there is an inverse correlation between the potency of a virus strain to invade the brain and induction of apoptosis [18]. Neurons, microglia and astrocytes also contribute to the viral proliferation via changing neuronal function [22].

HLA-G Expression

HLA-G1 molecule is expressed on the neurons due to stimulation of rabies virus. This molecule prevents the inflammatory function of natural killer (NK) and T cells in infectious conditions. In fact, the HLA-G molecule is attached to the inhibitory receptors of the NK and T cells and leads to the destruction of these cells. The inhibitory receptor KIR2DL4, NK cell-activating receptor with inhibitory potential, located on the NK cell and immunoglobulin inhibitory receptor (immunoglobulin like transcript (ILT)), such as ILT2 and ILT4 expressed on NK, TCDB+ and TCD4+ cells, are attached to the HLA-G molecule. On the other hand, HLA-G is able to develop tolerance-mediating dendritic cells by destructing the major histocompatibility complex (MHC) class II presentation pathway. Cytokines such as interferon beta also lead to the expression of the HLA-G molecule. In fact, following infection of the neuron with RV due to presence of HLA-G molecule on the neuron surface, occurs an adjustment of the immune response [21].

Discussion

The pathogenic agents should be able to inhibit and escape from immune system to cause chronic or fatal diseases. The virus is a lethal virus that leads to inhibition of the immune system responses using some mechanisms thus causes disease and death of the patient [3,22,23]. Studies showed that the components of intrinsic immunity as the first defense barrier cannot be activated quickly and stimulate the adaptive immunity for eradicating the disease. In addition, in this disease, performance of the immune system is highly limited due to special sensitivity and unusual structure of the nervous system. Therefore, due to limited immune responses, the disease progresses and the virus can continuously replicate and ultimately, acute and progressive encephalitis leads to the death of the patient [22]. Rabies is still prevalent in developing countries, affecting populations with limited access to health care. Human exposure to potentially rabies-infected animals is a public health concern worldwide. Thus, according to the WHO recommendation, individuals at-risk of rabies virus including rabies researchers, veterinarians, wildlife workers, dog breeders, animal handlers and veterinary students should receive rabies pre-exposure prophylaxis (PrEP) [24].
