Abstract

Context: Pneumorrhachis (PR) is an uncommon condition characterized by the presence of air within the spinal canal. Usually it results following trauma or surgery involving spinal instrumentation. Spontaneous pneumorrhachis has also been described in association with spontaneous pneumomediastinum or secondary to marijuana smoking and cocaine snorting.

Findings: We report a case of spontaneous pneumorrhachis in a patient who was snorting cocaine along with nitrous oxide inhalation for recreation.

Conclusion: It is helpful to elicit a history of illicit drug use, particularly regarding cocaine in a case of spontaneous pneumorrhachis.

Keywords: Pneumothorax; Drug abuse; Spine non trauma

Case Report

A 19 year male came to emergency department with shortness of breath and pleuritic chest pain. He had a history of inhalation of nitrous oxide and cocaine. He denied any trauma or recent air travel. On clinical examination he was anxious and tachypneic. There was extensive crepitus over the neck and anterior chest. CT scan of the chest showed extensive subcutaneous emphysema with pneumo-mediastinum and interstitial emphysema. Traces of pneumothoraces were seen in the apices and air was seen in spinal canal at C7/T1 level (Figure 1a & 1b). CT scan of the brain was reported to be normal. The neurological examination was entirely normal. He was managed conservatively with high flow oxygen inhalation. He improved clinically after 48 hours and was subsequently discharged for outpatients follow up.

Discussion

Spontaneous pneumorrhachis is a rare entity, with one study reporting an incidence of 9.5% in a group of pediatric patient with newly diagnosed spontaneous pneumo-mediastinum [1]. Uses of illicit stimulants such as cocaine, amphetamines, and their derivatives have been associated with development of pneumo-mediastinum [2]. Crack cocaine is most commonly associated with respiratory complications requiring hospital admission. Injections of methamphetamine have also been associated with pneumo-mediastinum and subcutaneous emphysema, along with pneumorrhachis [3]. Pneumorrhachis is classified as internal, intra-dural, external, and extradural [4]. Intradural PR is recognized by the presence of pneumocephalus without a head trauma wherein the air originates from a dural tear from a penetrating spinal injury. Traumatic external (intraspinal or extradural) PR usually recovers uneventfully; Traumatic internal PR is associated with major trauma and can be considered a severity marker [5].

Pneumorrhachis has been reported to result from the rupture of high-pressure alveoli (Macklin phenomenon) secondary to an acute increase in the transalveolar pressure gradient during a Valsalva manoeuvre. The air then may enter cervical subcutaneous tissues, mediastinum, pericardium, and epidural space, in the latter via the neural foramina and along the vascular and nerve root sheaths [6].

Of all the reported cases of spontaneous PR, four were reported to have developed neurologic signs and symptoms [7-10]. All the cases recovered without any specific intervention.

CT scan is the imaging modality of choice for diagnosis but differentiation between internal and external PR is difficult. Spontaneous PR is usually self limiting and there are no
established guidelines for the management of spontaneous PR. It is usually treated conservatively as the air is reabsorbed by the bloodstream with no consequence. A thorough evaluation of patients presenting with clinical signs and symptoms of pneumomediastinum should include a meticulous neurologic evaluation and CT imaging of the neck and chest to assess for concurrent PR.

Figure 1: a) Axial view of C7 vertebra with air inside the canal. b) Corresponding sagittal view showing air in C7 and T1 neural foraminae.

Conclusion

Pneumorrachis is a self-limiting condition and resolves without any consequences. Prompt recognition of the underlying cause is essential for management planning. It is helpful to elicit a history of illicit drug use, particularly regarding amphetamines and cocaine.
