Abstract
Multiple myeloma (MM) is a hematological malignancy. Classically discovered during bone, hematological or renal manifestations. Myelomatous ascites is a rare extra-medullary manifestation associated with poor prognosis. We report a case of MM revealed by ascites as an initial manifestation of extramedullary involvement in a 56-year-old patient.

Keywords: Multiple myeloma; Hematological malignancy; Myelomatous; Etiological

Introduction
Multiple myeloma (MM), or plasma cell myeloma, is characterized by plasmocytic proliferation and the production of a large amount of specific immunoglobulins. The diagnosis is classically discovered on the occasion of bone, hematological or renal manifestations. Visceral disorders are rare and usually seen at an advanced stage [1]. We report a case of MM revealed by ascites secondary to peritoneal involvement in the context of extramedullary localization.

Case Report
A 56-year-old lady was admitted to our department for an etiological assessment of an oedema-ascitic syndrome. During the interview, the patient had a history of chronic renal insufficiency undergoing hemodialysis for 2 years (2 sessions per week).

During the general clinical examination, there was an alteration of the general state of health with asthenia and a loss of weight, without fever. A BMI at 17.2 kg/m² and a WHO score at 2. There was pitting edema of the lower limbs, bilateral. Examination of the abdomen revealed a diffuse sensitivity, with ascites of great abundance associated with homogeneous hepatomegaly, painless (hepatic arrow at 18cm). The remainder of the examination was normal including cardiovascular examination, without clinical signs of portal hypertension or hepatocellular insufficiency. The ganglionic areas were free.

A morphological assessment based on an abdominopelvic CT scan confirmed the existence of homogeneous ascites and hepatomegaly without evidence of portal hypertension or ovarian mass.

The exploratory puncture of the ascites fluid found a fluid poor in non-superinfected protein according to the following formula (protein content at 22g/L with albumin level at 11.9g/l) with leucocytes at 50 elements/mm³, 10% were neutrophils and 90% lymphocytes with 350 cells/mm³ cells. The direct examination did not isolate the germ with a sterile culture at 48 hours.

The other biological data were as follows: normocytic normochromic anemia at 9.3/dL, with reticulocyte level at 52.700/mm³, thrombocytopenia at 94 000/mm³ without leukocytosis or leukopenia. The transaminase activity was normal and anicteric cholestasis was noted: GGT at 113IU/l, alkaline phosphatase at 229IU/l, with total bilirubin at 7.6 μmol/L. The prothrombin rate was 63% and the factor V 85%.

A protein level of 64g/L was also noted with 32g/L albuminemia. Electrophoresis of plasma proteins showed monoclonal gammapathy. Immunofixation of serum proteins showed kappa light chain IgA monoclonal immunoglobulin. The 24-hour proteinuria was negative. The viral serologies B, C were negative.

The initial diagnostic hypothesis of ascites complicating chronic liver disease was quickly ruled out due to the absence of hepatic insufficiency and portal hypertension.

The myelogram was inconclusive. A bone marrow biopsy showed diffuse medullary infiltration by plasma cells with the...
presence of 20% dystrophic plasma cells (Figure 1). The diagnosis of MM with peritoneal involvement was made. The patient was transferred to the hematology department for specialized management (Figure 2).

Discussion

Approximately 70% of patients with plasmocytic tumors have extramedullary tumor infiltration [2]. The most common extramedullary involvement is the upper respiratory tract and the liver. The appearance of ascites in patients with myeloma is usually secondary to significant hepatic infiltration by plasma cells. It may also be secondary to heart failure, kidney damage or infectious peritonitis. In contrast, myeloma ascites caused by peritoneal infiltration of tumor cells are very rare as the case of our patient. They can inaugurate clinical manifestations or develop during the evolution of the disease [1,3].

The clinical cases of myelomatous ascites and pleural effusion reported in the literature are generally associated with a poor prognosis [4,5]. Karp and Shareef reported that median survival was 1.5 months in 9 patients with myelomatous ascites [3]. However, several cases of improvement under treatment with prolonged survival have been reported hence the interest of early diagnosis [6,7].

The IgA isotype represents a quarter of MM cases. 62.5% of patients with Myelomatous ascites have IgA isotype myeloma [1]. Higher levels of plasma IgA are associated with extramedullary effects. Lake et al. [8] hypothesized that the cause was higher IgA production by lymphoid cells in multiple myeloma, which may disproportionately affect extramedullary sites.

Conclusion

The diagnosis of MM is possible even in the absence of bone involvement or haematological or renal complications. These modes of extra-medullary revelation are rare and have poor prognosis.
