Introduction

Posterior dislocation of the shoulder joint is a rare entity accounting for less than 2% of all shoulder dislocations. The injury is misdiagnosed in 50% to 79% of patients, most commonly due to lack of critical physical examination and inadequate radiographic examination or insufficient radiograph reading skills of the attending physician. The main causes of dislocations are trauma, seizures, or electric shock[1-7]. The diagnosis is suspected in patients with a palpable prominence of the coracoid, increased palpable prominence of the humeral head in the posterior aspect of the shoulder, and a complete loss of external rotation [8].

An anteroposterior view and axillary view (if tolerated by patient) is helpful to reach the diagnosis[9]. Computed tomography can identify the involvement of the articular surface of the humeral head and fractures of the tuberosity, surgical neck, and glenoid. Magnetic resonance imaging is useful rare cases to reveal cuff tears and posterior labrum lesions. Treatment modalities vary and depend on the size of the humeral head defect, the duration of dislocation, and the degree of instability. Numerous surgical techniques have been described for the management of this injury, including disimpaction with elevation and bone grafting of the defect, transposition of the subscapularis tendon or the lesser tuberosity into the defect, rotational osteotomy of the proximal humerus, and hemi- or total shoulder arthroplasty for large defects and neglected dislocations[3-6].

Materials and Methods

Between January 2014 and December 2016, we performed retrospective analysis of four patients (5 shoulders) with locked neglected posterior shoulder dislocation treated by a single orthopedic surgeon in a private setting. Causes of posterior shoulder dislocation in our study were trauma in two cases while other two had electric shock. One case with electric shock was bilateral. The patients’ average age was 43 years (range 25-58 years), while the mean follow up was 11 months (range 6-18 months). All the patients in our series were males and the dominant shoulder was affected in 3 cases. All the patients were evaluated by plain radiographs pre and postoperatively. Each patient underwent open reduction and capsular shift with subsequent immobilization and physical therapy.

Surgical Technique

We performed an open reduction of the shoulder joint using deltopectoral approach with the patient in beach chair position under general anesthesia. The lower edge of the subscapularis tendon was identified and tagged with prolene suture[1-7]. The diagnosis is suspected in patients with a palpable prominence of the coracoid, increased palpable prominence of the humeral head in the posterior aspect of the shoulder, and a complete loss of external rotation [8].

Stability of the shoulder joint was evaluated preoperatively clinically and through fluoroscopy to see the entire range of motion. Temporary stabilization of shoulder joint with Kirschner wires was unnecessary. One patient required filling of the bone defect by lesser tuberosity. The wound was closed in layers using a suction drain. The shoulder was immobilized using a brace for a period of 6 weeks. We restricted Internal rotation of the shoulders during this time period. Physical therapy was initiated, including passive, active-assisted, and progressively active range of motion and rotator cuff strengthening exercises. Full activity was allowed at 12 weeks postoperatively.

Results

We use UCLA scoring system. Mean follow-up was 11 months (range, 6-18 months). Mean range of shoulder motion was 162° of flexion range, 150°-175°), 69° of external rotation (range, 55°-80°), 48° of internal rotation (range, 40°-55°), and 140° of abduction (range, 130°-155°). At last follow-up, all patients were asymptomatic with painless and stable shoulder joints without sign of instability. Mean Constant score used to evaluate patient satisfaction was 84% (range, 77%-90%). All patients were very satisfied with their level of function with no restrictions. In all cases, radiographs showed the humeral head to be satisfactory reduced in relation to the glenoid (Figures 1&2) and (Tables 1&2).

### Discussion

Posterior shoulder dislocation is a rare entity. Once it is diagnosed, the management depends on the amount of the defect of the humeral head and the time from injury. The size of the humeral head impaction fracture is key to the decision process [10]. Defects of the articular surface of the humeral head up 50% of the articular surface should be treated with shoulder arthroplasty [11,12]. The management of defects between 25% and 50% are more challenging. Our study has some short comings. There were small number of cases. We have short follow up and there was no comparative group [13-23].

### Conclusion

Management of neglected, locked posterior shoulder dislocation is difficult and diagnosis is often delayed, making treatment even more challenging. Traditional techniques have had limited success with closed reduction in the chronic situation. Open reduction is the mainstay of treatment in neglected locked posterior shoulder dislocation.
