Introduction

Parkinson's Disease (PD) is a chronic progressive disorder of the central nervous system, gradually impairing the functioning of those affected [1]. The prevalence of PD in the general population is about 0.15% and increases with age; 1.8% above 65 years of age and 2.6% above 85 years of age [2]. The essence of the pathological process underlying PD is degeneration and the disappearance of dopaminergic neurons in the substantia nigra of the midbrain. The development of the pathological process in PD lasts for many years and was divided by Braak into six stages. Characteristic inclusion bodies are present in all stages; Lewy neurites within the cellular spines and the round Lewy bodies within the nerve cells. However, Lewy neurites are not pathognomonic of PD, they were also found in the CA2-3 region of hippocampus in Alzheimer’s disease [3,4].

Lewy neurites and bodies occur in the central and peripheral nervous system and contain mainly neurofilament proteins: alpha-synuclein and ubiquitin. The neurodegenerative process in PD proceeds in a sequential manner starting from predisposed places in the spinal cord and the medulla oblongata, eventually taking up other susceptible regions of grey matter. Stage 1 involves degeneration of the dorsal motor nucleus of the vagal nerve, the adjoining reticular zone and the olfactory bulb. Similar pathological changes also appear in some neurons of the autonomic system, for example in the neurons of the Auerbach plexus. In the next pre-symptomatic stage, degenerative changes intensify and include the raphe nuclei, nucleus reticularis parvocellular and the locus coeruleus (stage 2). The substantia nigra becomes affected in stage 3, along with other basal portions of the midbrain and forebrain; Lewy neurites appear for the first time in the amygdala and in the nucleus basalis of Meynert. At this stage, after crossing the individual neuropathological threshold, symptoms of the disease appear [3,4]. In the next stage, the pathological process begins to involve the temporal mesocortex (stage 4), and in the final stages (stage 5 and 6) the entire neocortex is affected [4].

Symptoms of PD are often nonspecific, they are also associated with many other diseases and initially discreet. They can be preceded by pain diagnosed as sciatica, brachialis tendinitis and sometimes also olfactory disorders. Symptoms can include: reduced efficiency, general slowing down and impoverishment of movements, tremors, increased muscle tone, indistinct speech, balance disorders, sudden blockage...
of movement while walking, mental problems, dysphagia, depression and vegetative disorders. Parkinson's disease cannot be cured, but existing therapies can help control the symptoms. This could be achieved either by administration of medicines or surgical procedures [5].

**Discussion**

One of the first attempts to treat PD was supplementing the deficiency of dopamine. But since dopamine itself does not pass the blood-brain barrier, the administration of this neurotransmitter to the blood would have no effect. Researchers found that L-DOPA, the precursor from which dopamine is formed, does pass through the blood-brain barrier. The introduction of L-DOPA was a breakthrough in the fight against PD. L-DOPA is administered peripherally together with enzyme inhibitors converting L-DOPA into dopamine. These inhibitors do not cross the blood-brain barrier. In the dopaminergic neurons of the brain, L-DOPA is transformed into dopamine. Unfortunately, L-DOPA does not prevent the death of dopamine-producing cells. In most cases, the patient’s body responds positively to L-DOPA only for the first few years, and then, when the number of L-DOPA transforming neurons in dopamine decreases, it is necessary to increase the dose of L-DOPA, which leads to many undesirable side effects [6-10]. Another treatment strategy is to inhibit the degradation process of dopamine that has already been released from neurons which can be done by inhibiting the COMT or MAO-B enzymes. The administration of dopamine receptor agonists (substances that mimic the effects of dopamine) is also very common. Their task is to stimulate dopamine receptors in the brain [11-14].

One of the surgical strategies for the treatment of PD is transplantation of cells capable of producing dopamine; these cells can come directly from the patient’s body or from human foetuses. The use of cells derived from the patient proved ineffective as these cells are in small quantities and die rapidly after transplantation. In Sweden and The United States, treatments are performed involving the implantation of foetal brain tissue in patients with advanced PD. However, the use of cells originating from human foetuses for therapeutic purposes raises ethical issues [15-17].

The most promising method of treating PD is Deep Brain Stimulation (DBS). During DBS procedures, thin stimulating electrodes are implanted into deeply located parts of the brain [1]. Currently, around 130,000 people live in the world with a brain stimulator. The first DBS treatment in PD was carried out in 1987 in France. Shortly thereafter, it was used in other countries. In 2002, the Food and Drug Administration (FDA) granted approval for treatment of Parkinson’s disease patients with DBS. The implanted electrodes generate electrical impulses that modify the action of the nerve centres responsible for the development of the disease. The pulse generator installed in the patient’s body provides a constant source of current. The voltage is very low: 0.1 - 5 V [1,18-21].

In Parkinson's disease, the electrode is usually implanted in the subthalamic nucleus, less often in the internal globus pallidus or in the lateral nucleus [22]. Interestingly, the cerebral electrode is not implanted in the substantia nigra (the place where dopamine neurons seem to be atrophied in PD) because DBS causes the inhibition of selected nerve structures, not their stimulation. Implantation of an electrode into a substantia nigra would therefore have the opposite effect. Under physiological conditions, dopamine balances other nerve centres and inhibits some of them (i.e., STN). In Parkinson’s Disease, in the absence of dopamine, there is disinhibition of certain structures, resulting in the appearance of motor symptoms (stiffness, tremors, dyskinesia) [23]. Deep brain stimulation restores balance in the brain centres, relieving the symptoms of PD [1].

The DBS treatment in Parkinson’s disease is extremely effective. It allows for significant improvement in movements, reduction of muscle stiffness, hand tremors and reduction of dyskinesia [1]. In the analysis of many studies on DBS in Parkinson’s disease, the average improvement in mobility was rated at 52%. This value is averaged based on neurological assessments of patients before and after surgery. The DBS effect assessment is based on the analysis of the quality of life of patients in their daily activities; the DBS effect is usually even greater [24-26]. In 2013 we published a paper [1] raising hope for DBS in PD treatment. However, we would like to mention some side effects associated with DBS in this review. Having said that, DBS is highly recommended for those severely affected by PD with low quality of life. Any surgery involves risk, particularly when it involves the brain’s delicate structures. There is a risk of bleeding or infection after the procedure. Side effects resulting from stimulation include: the possibility of speech deterioration, emotional disorders (depression, hypomania, suicide attempts) and the risk of deterioration of cognitive functions (mainly in terms of executive functions and verbal fluency) [27,28].

In 2017, a team of scientists published a paper titled “Noninvasive deep brain stimulation via temporally interfering electric fields” giving a new hope to PD patients. Grossman et al. conducted experiments proving that DBS is possible without invasive surgery. Basically, the stainless-steel plate was affixed to the skull of mice and electrodes were connected to the plate. Then a low to high frequency (10 Hz - 2 kHz) electric current was applied and the demodulating of neurons was observed. These experiments are very promising, however, extensive studies in this direction is needed [29,30].
